## Decreasing emissions of NMVOC and SO<sub>2</sub>, NO<sub>x</sub> reduction still lagging

The industrial emissions of NMVOC and SO<sub>2</sub> have decreased markedly since 1990: the emissions of NMVOC have more than halved, while the emissions of SO<sub>2</sub> have decreased by 63 %. The chemical (-55 %) and metal sectors (-64 %) and the paper industry (-50 %) in particular have been able to reduce their emissions by the use of low solvent content products, vapour recovery and production optimization. The large reduction in SO<sub>2</sub> can mostly be explained by the reductions in the chemical and metal sectors in the first half of the 1990s. Despite the major reductions, SO<sub>2</sub> remains the most important source of acidifying emissions within the industry. These SO<sub>2</sub> emissions, which are largely due to combustion emissions, can be reduced further by the use of low-sulphur fuels (natural gas) and a higher energy efficiency.

In contrast to SO<sub>2</sub> and NMVOC, the NO<sub>x</sub> emissions remain almost stable (-1 % compared to 1990): the emissions increased between 1990 and 1995 by 29 %, thereafter a small decreasing trend can be observed. The chemical sector, that was responsible in 2007 for 42 % of the total industrial NO<sub>x</sub> emissions, succeeded in reducing the emissions by 8 % between 1990 and 2007. The textile industry reduced the emissions as well (-64 %), but the metal sector (+7 %), food sector (+7 %) and the paper industry (+6 %) emitted more in 2007 than in 1990. A reduction can be achieved by the increased use of NO<sub>x</sub> filters, low NO<sub>x</sub> burners and catalytic converters.
